Keywords: Familial adenomatous polyposis, *APC*-gene, *MUTYH*-gene, guidelines, management

Abstract

Familial adenomatous polyposis (FAP) is a well-described inherited syndrome, which is responsible for <1% of all colorectal cancer (CRC) cases. The syndrome is characterized by the development of hundreds to thousands of adenomas in the colorectum. Almost all patients will develop CRC if they are not identified and treated at an early stage. The syndrome is inherited as an autosomal dominant trait and caused by mutations in the *APC*-gene. Recently, a second gene has been identified that also gives rise to colonic adenomatous polyposis, although the phenotype is less severe than typical FAP. The gene is the *MUTYH*-gene and the inheritance is autosomal recessive.

In April 2006 and February 2007, a workshop was organized in Mallorca by European experts on Hereditary Gastrointestinal Cancer aiming to establish guidelines for the clinical management of FAP and to initiate collaborative studies. Thirty-one experts from nine European countries participated in these workshops. Prior to the meeting, various participants examined the most important management issues according to the latest publications. A systematic literature search using Pubmed and reference lists of retrieved articles, and manual searches of relevant articles was performed. During the workshop all recommendations were discussed in detail. Because most of the studies that form the basis for the recommendations were descriptive and/or retrospective in nature, many of them were based on expert opinion. The guidelines described in this manuscript may be helpful in the appropriate management of FAP families. In order to improve the care of these families further, prospective controlled studies should be undertaken.

Introduction

In about 5% of all cases, colorectal cancer (CRC) is associated with a dominantly or recessively inherited syndrome due to mutations in high penetrance genes. The most common syndrome is Lynch syndrome (hereditary non-polyposis colorectal cancer (HNPCC)), which is characterized by the development of colorectal cancer, endometrial cancer and various other cancers(1). The syndrome is caused by a mutation in one of the mismatch repair (MMR) genes: *MLH1*, *MSH2*, *MSH6* and *PMS2*. Familial adenomatous polyposis (FAP) is another well-described inherited syndrome, which is responsible for 1% or less of all CRC cases(2). This syndrome is characterized by the development of hundreds to thousands of adenomas in the colorectum as well as several extracolonic manifestations. Almost all patients will develop CRC if they are not identified and treated at an early stage(3). Approximately 8% of families with FAP display an attenuated form of FAP characterized by the development of fewer adenomas and CRC at a more advanced age(4). The syndrome, when autosomal dominantly inherited, is caused by mutations in the *APC*-gene. This gene plays a central role in the development and homeostasis of the intestine and many other tissues. Recently another polyposis gene has been identified, the *MUTYH* gene, in which bi-allelic mutations cause an autosomal recessive pattern of inheritance(5). This form of polyposis is usually referred to as *MUTYH*-associated polyposis (MAP).

In April 2006 and February 2007, a workshop was organized for a group of European experts on hereditary GI-cancer. The main purpose was to develop guidelines for the clinical management of the most common inherited forms of CRC and to establish

collaborative studies. A total of 31 experts from nine European countries participated in the workshops. These experts included clinical and molecular geneticists, surgeons, gastroenterologists and a pathologist all involved in the management of hereditary CRC. Prior to the meetings, key questions for important management issues were identified and a literature search was performed in order to address these questions and to elaborate guidelines in the light of the most recent knowledge. In this manuscript we report the outcome of the discussion with respect to FAP. Search terms included familial adenomatous polyposis (FAP), *MUTYH*-associated polyposis (MAP), *APC*-gene, and *M(UT)YH*-gene. Only peer-reviewed English-language articles were included. The criteria that were used for evaluation of studies and assessment of the category of evidence and strength of the recommendation are shown in Table 1. During the workshop all recommendations were discussed in detail.

Table 1. Validity and grading of recommendations.

CATEGORY OF EVIDENCE		GRADING OF RECOMMENDATIONS
Meta-analysis of randomised controlled trials	Ia	A
Randomised controlled trial	Ib	
Well-designed controlled study without randomisation	IIa	B
Well designed quasi-experimental study	IIb	
Non-experimental descriptive study	III	C
Expert opinion	IV	

Characteristics of *APC*-associated FAP

Familial adenomatous polyposis is an autosomal dominant condition caused by *APC* mutations that occurs in one in 10.000 births(6). In 15-20%, the cases are "de novo" without clinical or genetic evidence of FAP in the parents(7). Recent studies indicated the presence of mosaicism in approximately 15% of such cases(8;9). Most patients develop hundreds of colorectal adenomas during childhood and adolescence. Without surgical intervention they almost inevitably develop CRC by the mean age of 40-50 yrs. A milder form of FAP (attenuated FAP, AFAP) characterized by the presence of fewer adenomas and later onset of disease is observed in approximately 8% of cases(10). Adenomatous polyps also develop in the upper-GI-tract, especially in the duodenum and if untreated, these progress to malignancy in approximately 5% of cases(11). Gastric fundic gland polyps and adenomas in the antrum also occur. There are a few case reports (12;13) of gastric cancer in FAP, especially from Japan and Korea, but substantial evidence of an increased risk in FAP patients from Western countries is not available. The incidence of gastric cancer in large national polyposis registries do not support the hypothesis of an increased risk, but only future large multicenter studies can clarify if the known cases represent an increased risk or mere coincidence. There is an increased risk of malignancy at other sites including the brain, thyroid and the liver. Deregulation of the *APC*-gene has been shown to play a role in carcinogenesis in all of these tissues. Desmoid tumours occur in at least 10-15% of cases(14). Although these tumours of connective tissue are histologically benign they can lead to life-threatening complications through their size and impingement on vital structures. Other features observed in FAP are shown in Table 2.

Table 2. Extra-intestinal features in familial adenomatous polyposis

<u>Benign lesions:</u>	<u>Malignant lesions:</u>
-congenital hypertrophy of the retinal pigmented epithelium (70-80%) -epidermoid cysts (50%) -osteoma (50-90%) -desmoid tumour (10-15%) -supernumerary teeth (11-27%) -adrenal gland adenomas (7-13%)	-thyroid cancer (2-3%) -brain tumour (<1%) -hepatoblastoma (~1%)

The standard clinical diagnosis of typical/classical FAP is based on the identification of more than 100 colorectal adenomatous polyps. The clinical diagnosis of AFAP is more difficult. Recently, diagnostic criteria for AFAP have been proposed by Nielsen and by Knudsen(4). According to the criteria suggested by Nielsen there should be (a) at least two patients with 10-99 adenomas at age >30 yrs or (b) one patient with 10-99 adenomas at age >30 years and a first-degree relative with CRC with few adenomas, and applying for both criteria, no family members with more than 100 adenomas before the age of 30 years. Based on a multicenter study of 196 patients, Knudsen et al. proposed the following diagnostic criteria for AFAP: (a) a dominant mode of inheritance and (b) 3-99 colorectal adenomas at age 20 or older (presented at the meeting of the International Society of Gastrointestinal Hereditary Tumours (InSiGHT), Yokohama 2007)

In more than 70% of patients with typical FAP a mutation can be identified in the *APC*-gene. The yield of *APC*-gene mutations is much lower in patients with AFAP (circa 25%)(4). Genetic counselling and mutation analysis should be offered to all patients with FAP. If a pathogenic mutation has been identified in the index patient, predictive testing for the mutation should be offered to the first-degree relatives. In typical FAP, family members that are found to carry the mutation should be advised to undergo periodic examination of the rectosigmoid from the early teens and of the upper GI- tract from age 25-30 years to monitor adenoma development. The treatment of colonic polyposis consists of colectomy or proctocolectomy usually once florid polyposis has developed. The treatment of duodenal adenomas depends on the severity of the disease.

Surveillance of the colorectum

QUESTION: Does periodic examination of the colorectum lead to early detection of familial adenomatous polyposis and reduction of CRC - associated mortality?

A literature search showed that at least five studies have addressed the first part of the question (15-19). These studies described the results of polyposis registers that were established in various countries mostly in the 1980's and 1990's in order to improve the prognosis of patients with this disease. All studies showed that in symptomatic FAP cases, the incidence of CRC was much higher (incidence: 50-70%) than in those that were identified by surveillance (incidence: 3-10%) initiated by the registries. Other studies that evaluated the mortality of patients with FAP reported that surveillance policies and prophylactic colectomy have resulted in a reduction in the number of FAP patients that died from CRC but that nowadays, a greater proportion of deaths is attributable to extracolonic manifestations of the disease (desmoid tumours, duodenal cancer) (20-22). At least three studies have indicated that central

registration and prophylactic examination led to a reduction of CRC-associated mortality (23-25).

CONCLUSION: *Surveillance of FAP-patients leads to reduction of CRC and CRC-associated mortality (Category of evidence III).*

QUESTION: *What is the optimal surveillance protocol in terms of timing, type of investigation and surveillance interval in patients with classical FAP and AFAP?*

Classical (Typical) FAP

The age at which screening should start depends on the risk of malignant transformation of the colorectal adenomas(26). In the recent literature there are no studies that provide information on the distribution of the ages at diagnosis of CRC in FAP because most cases are currently diagnosed in a premalignant stage. Studies on large series of FAP families from the 1970's and 1980's indicated that the risk of developing CRC before age 20 is very low(16). The proportion of FAP-patients with CRC diagnosed \leq age 20 years observed in some European registries is shown in Table 3.

Table 3. Proportion of FAP-patients with CRC diagnosed \leq age of 20 yrs.*

Polyposis registry	Total number of CRC	Number of CRC (%) diagnosed		
		0-10 years	11-15 years	16-20 years
Netherlands	106	0	1	1
Denmark	190	0	0	3
Germany	524	0	1	7
St Mark's	96	0	0	3
Finland	157	0	0	1
Total	1073	0	2 (0.2%)	15 (1.3%)

* communicated with registries

There were no cases of CRC at or before the age of 10 years and an incidental case between age 11 and 15 years. Based on these findings, the European group advises starting endoscopic surveillance from the early teens. Since some patients, especially those with a mutation located at codon 1309 in the *APC*-gene (see below), may develop severe polyposis of the colorectum before the age of 10, attention must be paid to FAP-related symptoms(27). These symptoms may include increasing bowel movements, looser stools, mucous discharge, rectal bleeding, abdominal or back pain. In symptomatic patients endoscopic investigation may be indicated at any age.

In family members with an identified mutation, endoscopic surveillance should be continued lifelong because the penetrance of the disease is virtually 100%. In high risk members (first-degree relatives of affected patients) from families without an identified *APC*-mutation, surveillance should be continued until age 50.

The second question is which part of the colorectum should be investigated. Only one study was found that specifically addressed this question. In that study Bussey demonstrated that in 170 patients with FAP, the rectum was affected in all cases(16). Based on these studies it is sufficient to perform flexible sigmoidoscopy, at least initially. Once adenomas are identified with sigmoidoscopy, there is an indication for full colonoscopy.

Regarding the interval between examinations, studies on the natural history of FAP showed that it takes on average 15-20 years from the first development of adenomas to the development of malignancy (16). Therefore, an interval of two years between

normal sigmoidoscopies is appropriate. If adenomas are detected colonoscopic investigations should be performed annually until colectomy is planned. In high risk members (first-degree relatives of affected patients) from families without an identified *APC*-mutation, surveillance should be continued at two yearly intervals until age 40. After this age the intervals between examinations may be longer, for example, every 3-5 yrs and surveillance may be discontinued at age 50.

AFAP

In families with AFAP, a different protocol is recommended. A recent Dutch study on nine AFAP families associated with *APC*-mutation, reported a mean age at diagnosis of CRC of 54 years (n=40) which is about 10-15 years later than in classical FAP. No cases of CRC were observed in individuals younger than 20 years. The youngest case of CRC was diagnosed at age 24 years(4). In an American study of a large family with AFAP, no CRC was observed in patients under the age of 29 years(28). Therefore, periodic examination is recommended starting from age 18-20. Because patients with AFAP have been described that develop only a few adenomas localized in the right part of the colon, colonoscopy is recommended in stead of sigmoidoscopy. **CONCLUSION:** *The suggested surveillance protocol for patients with classical and attenuated FAP is summarized in Table 4. (Category of evidence III, grade of recommendation B)*

Table 4. Colorectal surveillance protocol in family members at risk for (A)FAP

	Type of investigation	Lower age limit	Interval
Classical FAP	Sigmoidoscopy*	10-12 yr	2 yr*
AFAP	Colonoscopy	18-20 yr	2 yr*

*Once adenomas are detected annual colonoscopy should be performed until colectomy is planned.

Management of colonic polyposis

Removal of the colon with polyposis at a premalignant stage is very important because it prevents the significant morbidity and mortality associated with advanced colorectal cancer.

QUESTION: *Which surgical procedure is the best option for patients with FAP?*

The two main options of prophylactic removal of the large intestine are colectomy with ileorectal anastomosis (IRA) and proctocolectomy with ileal pouch-anal anastomosis (IPAA). IRA is a relatively simple and straightforward operation, compared to IPAA. The complication rate is relatively low and the bowel function postoperatively is almost always good. For IPAA, more extensive surgery is needed including pelvic dissection with its risk of hemorrhage, reduction of fertility in women and potential damage to pelvic nerves(29). Recently, a meta-analysis by Aziz et al has been published of studies that compared adverse effects, functional outcome and quality of life between the two options(30). The authors selected twelve studies containing 1002 patients with FAP. They reported that bowel frequency, night defecation and use of incontinence pads were significantly less in the IRA-group, although faecal urgency was more frequent with IRA compared to IPAA. Reoperation within 30 days was more common after IPAA. There was no significant difference between the procedures in terms of sexual dysfunction, dietary restriction or postoperative complications. Rectal cancer was only observed in the IRA-group (5%). In addition, abdominal reoperation on the rectum was more frequent after IRA (28%)

versus IPAA (3%). The study demonstrated the individual merits and weaknesses of IRA and IPAA.

An IPAA is the treatment of choice if the patient has a large number of rectal adenomas for example more than 15-20 adenomas. In patients with only a few rectal adenomas or with a polyp-free rectum both options are possible and the decision can be made on an individual basis.

Several studies have shown that the severity of colonic polyposis is correlated with the site of the mutation in the *APC*-gene. These studies have recently been reviewed by Nieuwenhuis et al(31). The evaluation showed that mutations between codon 1250 and 1464, especially those with a mutation at codon 1309 are associated with a severe form of FAP, mutations localized at the extreme ends of the gene and in the alternatively spliced part of exon 9 are associated with a mild form of FAP and an intermediate expression of disease is found in patients with mutations in the remaining parts of the gene. Several authors have proposed to use the outcome of genetic testing in guiding the surgical treatment of patients with a relatively polyp-free rectum(32-36). An IPAA may be advised in such patients with a severe genotype because such patients are at increased risk of developing severe rectal polyposis that will require a secondary proctectomy if IRA is performed(33-35). An IRA is indicated in those with a mild genotype because of the low risk of developing severe rectal polyposis(35;36). However, a consensus has not yet been reached by the Mallorca group, or more widely, on use of genotype as a decision aid to guide the choice of IRA or IPAA in patients with FAP who have no or little evidence of rectal polyposis(37).

Other factors that should be taken into account are fertility and desmoid development. Studies reported that fertility was significantly reduced after IPAA compared to IRA in women with FAP (38). Therefore, in young women who wish to have children, an IPAA should be avoided or postponed, if possible. In patients with desmoids it has been reported that conversion of IRA to IPAA might be difficult due to (asymptomatic) mesenteric desmoid tumours and shortening of the mesentery. For this reason, a primary IPAA might be the best option in patients with an increased risk of desmoid development, e.g. patients with a positive family history for these tumors or patients with a mutation located distal to codon 1444. Some members of the Mallorca group noted however that patients with mutations 3' of 1444_ often have mild polyposis in which performing an IPAA might be overtreatment.

In conclusion, the decision on the type of surgery depends on many factors. It should be emphasized that the final decision on the type of surgery lies with the patient after being fully informed about the natural history of the disease and the pros and cons of the main surgical options.

There are no guidelines regarding the timing of surgery. In general, a (procto)colectomy is indicated if there are large numbers of adenomas larger than 5 mm including adenomas showing a high degree of dysplasia. Most patients with classical FAP undergo surgery between age 15 and 25 years.

The frequency of endoscopic follow-up of the rectum after IRA depends of the severity of rectal polyposis. The recommended interval varies between 3 and 6 months. In patients with multiple large (> 5mm) rectal adenomas that show a high degree of dysplasia there is an indication for proctectomy. Because patients with IPAA may also develop adenomas and even cancer in the pouch, follow-up is indicated after this procedure at intervals of 6-12 months(39-42).

CONCLUSION: *The main surgical options of removal of the colorectum, i.e. total colectomy with ileorectal anastomosis (IRA) and proctocolectomy with ileo-pouch*

anal anastomosis (IPAA) both have their individual merits and weaknesses. The decision on the type of colorectal surgery in patients with FAP depends on many factors including the age of the patient, the severity of rectal (and colonic) polyposis, the wish to have children, the risk of developing desmoids and possibly the site of the mutation in the APC-gene. The final decision lies with the patient after being fully informed about the natural history of the disease and the pros and cons of the available surgical options. The group advises that IPAA should preferably be performed in expert centres.

Surveillance of the duodenum

Many studies have shown that adenomas in the duodenum can be found in 50-90% of cases (43;44). Age appears to be the most important risk factor. There is no clear association between site of the mutation and development of (severe) duodenal polyposis. In most studies the severity of duodenal polyposis is assessed using the Spigelman Classification(45). This system describes five (O-IV) stages (Table 5). Points are accumulated for number, size, histology and severity of dysplasia of polyps. Stage I (1-4 points) indicates mild disease whereas stage III-IV (>6 points) implies severe duodenal polyposis. Approximately, 80 % of the patients have stage I-III disease and 10-20% stage IV disease.

Table 5. Spigelman Classification for duodenal polyposis in FAP

Criterion	1 point	2 points	3 points
Polyp number	1-4	5-20	>20
Polyp size (mm)	1-4	5-10	>10
Histology	Tubular	Tubulovillous	Villous
Dysplasia	Mild*	Moderate*	Severe**

Stage 0, 0 points; stage I, 1-4 points; stage II, 5-6 points; stage III, 7-8 points; stage IV, 9-12 points; * is low degree of dysplasia according to current classification, ** high degree of dysplasia

QUESTION: Does periodic examination of the upper GI-tract lead to detection of duodenal polyposis in an early stage?

There are three prospective studies of surveillance of the duodenum (Table 6)(44;46;47). These studies demonstrated slow progression of duodenal polyps in size, number and histology. The risk of developing cancer appears to be related to the Spigelman stage. In the British study (Groves et al), 4 out of 11 patients with stage IV disease at initial examination developed cancer as did one out of 41 patients with initially stage III disease. In the Scandinavian-Dutch study (Bulow et al), two out of 27 patients with stage IV disease at the first endoscopy developed cancer compared with 2 out of 339 (<1%) with stage 0-III. The cumulative risk of duodenal cancer at age 57 was 4.5%.

Table 6. The progression of duodenal polyposis in familial adenomatous polyposis.

Author	Groves	Saurin	Bülow
Year of publication	2002	2004	2004
Subjects	99	35	368
Mean age (yrs)	42	37	25
Sex (% male)	55%	57%	49%
Mean follow-up	10 yrs	4 yrs	7.6 yrs
Spigelman stage IV			

-at initial examination	9.6%	14%	7%
-at last follow-up	14%	35%	15%
Duodenal cancer during follow-up	6*	0	4**

* Spigelman stage at previous endoscopy: II, III, IV, IV, IV, IV

** Spigelman stage at previous endoscopy: II, III, IV, IV

CONCLUSION: *Prospective follow-up studies on the natural history of duodenal polyposis have demonstrated that the adenomas progress slowly to cancer. Because the conversion from adenomas to carcinoma may take more than 15-20 yrs, current screening protocols of the upper GI-tract usually detect duodenal disease at a premalignant stage (Category of Evidence III)*

Management of duodenal polyposis

QUESTION: *Does treatment of premalignant duodenal lesions lead to a reduction of mortality related to duodenal cancer?*

In the literature, there are no studies in which surveillance and treatment of duodenal disease is compared with a strategy of no surveillance. Although the overall risk of developing duodenal cancer in all patients with FAP is relatively low (circa 5%)(11), the risk of developing cancer in patients with Spigelman stage III-IV duodenal adenomatosis is much higher (7-36%)(44;46). Identification of such patients is important because particularly this category of patients might benefit from intensive surveillance and early treatment.

The options of treatment are endoscopic and surgical. Endoscopic treatment includes snare excision, thermal ablation, argon plasma coagulation or photodynamic therapy. There are only a few studies that evaluated the outcome of endoscopic treatment. These studies have recently been reviewed by Brosens et al(48). The review demonstrated that the recurrence rate of adenoma development after endoscopic treatment is high (>50%) and that the treatment is associated with a high complication rate (perforation, haemorrhage, pancreatitis)(17%).

There is no consensus about how to treat patients with duodenal polyposis. In patients with only a few small adenomas (Spigelman stage I and II), the risk of developing duodenal cancer is very low and in view of the potential serious complications associated with (endoscopic) treatment, the management may be limited to follow-up. In patients with multiple larger adenomas (Spigelman stage III or more), the risk of duodenal cancer is higher. Because it is impossible to remove all adenomas, an appropriate approach might be to remove only large adenomas, e.g. those of more than 1 cm in diameter, or adenomas with a high degree of dysplasia. However, duodenal adenomas are usually flat and therefore difficult to remove. For these cases prior submucosal saline/adrenaline injection may facilitate removal and reduce the risk of haemorrhage and perforation. Although the value of endoscopic treatment of patients with stage II and III is unknown, a possible advantage of endoscopic treatment is that it may delay major intervention (e.g. Whipple's procedure) which is associated with a significant morbidity (20-30%) and even mortality. The Mallorca group advises centralization of such treatment in a few expert centres.

The options for surgical treatment of duodenal polyposis in FAP include local surgical treatment (duodenotomy with polypectomy and/or ampullectomy), pancreas-sparing duodenectomy and (pylorus sparing) pancreaticoduodenectomy (Whipple's procedure). At least 11 studies, also reviewed by Brosens et al. evaluated the outcome of local treatment of duodenal polyposis(48). Most studies reported a high recurrence

rate after local surgery in FAP patients with severe polyposis. The most important advantage of this treatment is that it may postpone major surgery in young patients. Duodenotomy might be especially useful in patients with one or two dominant worrisome duodenal lesions in an otherwise minimally involved intestine. In patients with stage IV disease found at repeated endoscopic examinations, there is an indication for pancreaticoduodenectomy or a pancreas sparing duodenectomy. Brosens et al. identified twelve studies that evaluated the outcome of this treatment. All studies showed that the recurrence rate of adenomas (in the proximal small bowel) was relatively low. However, in order to be able to investigate this part of the small bowel after surgery, the Roux-Y should be constructed in such a way that endoscopic follow-up is possible. The specific choice of procedure depends of the local expertise.

CONCLUSION: *Screening of the duodenum in patients with FAP may lead to the identification of patients with advanced duodenal disease (Spigelman stage III/IV). Intensive surveillance and treatment of such patients may lead to reduction of duodenal cancer related mortality (Category of evidence III/IV). In young patients (<40 years) with advanced disease (stage III/IV), local surgery (duodenotomy and polypectomy) might be of benefit to postpone major surgery. In older patients with stage IV disease at repeated examinations, there is an indication for duodenectomy (Category of evidence IV, Grade of recommendation C).*

QUESTION: *What is the appropriate protocol in terms of timing, type of investigation and surveillance interval?*

There is no consensus in the literature regarding the age at which upper GI-tract surveillance should be initiated. Some authors advise to start at the diagnosis of FAP, others from the age of 25-30 yrs. Evaluation of all cases of duodenal cancer reported in the literature showed that diagnosis before age 30 years is extremely rare(48). Therefore, the Mallorca group recommends to start from an age between 25 and 30 years. Most centres recommend the use of a side-viewing endoscope to allow detailed inspection of the Papilla, the predelicted site for duodenal polyposis. However, in the early Spigelman stages, the use of a forward-viewing endoscope might also be appropriate. The recommended intervals between screening depend on the severity of disease (Tabel 7)(44;46).

CONCLUSION: *The Mallorca group recommends that surveillance of the upper-GI-tract be initiated between age 25 and 30 years. The suggested protocol is shown in Table 7. (Category of evidence IV, grade of recommendation C).*

Table 7. Recommended surveillance interval between upper GI-endoscopic examination in relation with Spigelman classification

IV	Consider surgery

Management of desmoid tumours

QUESTION: *What is the appropriate treatment of desmoid tumours?*

A substantial number of FAP patients (at least 10-15%) develop desmoid tumours. Possible risk factors include abdominal surgery, positive family history for desmoids and site of the mutation (mutations beyond codon 1444)(14;49-51). In contrast to sporadic desmoid tumours, the majority of the tumours associated with FAP are

located in the abdominal wall or intra-abdominally. The tumours can be diagnosed by CT-scanning or MRI. The latter procedure may also provide information on the activity of the tumour. Desmoid tumours are also frequently encountered incidentally in patients requiring further surgery. The options for treatment are pharmacological treatment (NSAIDs and/or anti-estrogens), chemotherapy, surgical excision or radiotherapy (52-54). Evidence for the efficacy of these treatments is poor and is based on small, non-controlled studies. An additional problem for the evaluation of efficacy is that desmoids have a variable natural history with some tumors showing spontaneous regression in the absence of treatment.

In 2003, Janinis et al performed a systematic review of published clinical trials, studies and case series that reported the effectiveness of pharmacological treatment of desmoid tumours(55). The authors concluded that the evidence in the literature supports the opinion that both non-cytotoxic and cytotoxic chemotherapies are effective against desmoid tumours. However, the lack of sufficient patient numbers and randomized trials compromises the validity of the reported results and mandates further investigation with prospective studies including larger patient numbers.

In 2000, a review of the literature was published on the effectiveness of surgery compared to radiation therapy for (non-FAP) patients with desmoid tumours(56). The study showed that radiation therapy alone or in combination with surgery resulted in significantly better control than surgery.

Currently, the first line of treatment in patients with large or growing intra-abdominal or abdominal wall tumours is sulindac (300 mg) usually in combination with tamoxifen (40-120 mg) or toremifene (180 mg) (52-54;57). In patients with progressive intra-abdominal tumours that do not respond to this treatment, chemotherapy (e.g. doxorubicine and dacarbazine or methotrexate and vinblastin)(58;59) or radiation therapy is indicated. The preferred treatment of patients with an abdominal wall desmoid tumour is controversial. Some authors consider surgery of abdominal wall desmoid tumours as a reasonable first-line treatment in these cases (54). Others do not recommend surgery as primary treatment because most especially large tumours cannot be resected and the recurrence rate is high(60). There is also no agreement about the role of surgery for mesenteric desmoids. Some investigators consider surgery contra-indicated because of the risk of severe complications (short bowel syndrome, severe bleeding) or because surgery may trigger further growth of the tumor(52;60). These investigators recommend only minimal surgery (intestinal bypass) in patients with obstruction or advise stenting of the ureter in patients with ureteric involvement. Others, however, reported succesful excision of large mesenteric desmoids with low mortality and limited loss of the small bowel (61;62)and consider that resection of mesenteric desmoids in experienced hands may have a role in the treatment of selected patients unresponsive to conservative treatment

CONCLUSION: *Non-randomised, non-controlled studies suggest that sulindac in combination with tamoxifen is effective in FAP patients with intra-abdominal desmoids and desmoids located at the abdominal wall (Category of evidence III). Also small non-controlled studies indicate that chemotherapy or radiotherapy may be of benefit in those with progressive growing desmoids (Category of evidence III). The role of surgery of (intra)-abdominal-(wall) tumors is controversial (Category of evidence III)*

Pharmacological treatment

QUESTION: *What is the role of NSAIDs in the treatment of colorectal and duodenal adenomas in FAP?*

The first drug that was shown to be effective in FAP was sulindac(63-66). Longterm use of this drug reduced the number of colorectal adenomas by >50% in the colon as well as in the retained rectal segment of FAP patients after initial colectomy (63-67). However, sulindac did not prevent development of adenomas in FAP(68).

In the 1990s, selective COX-2 inhibitors were developed that were reported to have less (GI-related) side effects than the classical nonselective NSAIDs. One of these drugs (celecoxib) was found to reduce the number of colorectal adenomas by 28% (69). In contrast with sulindac, this drug also reduced the number of duodenal adenomas (70). Unfortunately, cardiovascular side-effects have recently been reported in patients using another selective COX-2 inhibitor, rofecoxib. In a trial involving 2600 patients with colon polyps, 3.5% of the patients assigned to rofecoxib had a myocardial infarction or stroke, as compared with 1.9 % of the patients assigned to placebo, necessitating premature cessation of the trial (71;72). A recently published meta-analysis of different NSAIDs confirmed the increased risk of cardiovascular diseases in rofecoxib(73). The analysis included 11 studies that reported on celecoxib. It was found that celecoxib exposure in a dose around 200 mg per day did not lead to an elevation of the risk of cardiovascular disease, but the data did not exclude an increased risk with higher doses which are usually indicated in FAP. Celecoxib (onsenar) is registered for the treatment of FAP in several countries, but some specialists who are dealing with the management of FAP patients are reluctant to prescribe these drugs especially because most patients have to use the drug in high doses on a longterm basis. Data are currently being collected on a worldwide basis to evaluate the effect and possible side-effects of the longterm use of celecoxib in patients with FAP.

Although NSAIDs do not replace surgical treatment for colonic FAP, they may yet play a role in postponing surgery in patients with mild colonic polyposis or patients with rectal polyposis after prior colectomy. They may also be used in patients who refuse surgical treatment or in patients that cannot be operated on because of extensive desmoid disease. Although the effect of celecoxib on the number of colorectal adenomas has never been directly compared with the effect of sulindac, the published trials suggest a stronger effect of the latter. In addition, an association of sulindac with serious cardiovascular side-effects has never been reported and the GI-related toxicity can be treated with proton pump inhibitors if necessary. Based on these considerations, one may argue that sulindac is more attractive than celecoxib for the treatment of colorectal adenoma.

Regarding the treatment of duodenal polyposis, the use of celecoxib might be justifiable for patients with severe duodenal polyposis (Spigelman stage III or IV), because the endoscopic and surgical treatment options in such cases are associated with significant complications.

CONCLUSION: *Chemoprevention with NSAIDs can be considered in patients following initial prophylactic surgery as an adjunct to endoscopic surveillance, to reduce the rectal polyp burden. The role of selective COX-2 inhibitors in patients with FAP is controversial because of cardiovascular side-effects reported for rofecoxib. Therefore, these drugs should only be considered in selected patients without cardiovascular risk factors until more data are available.*

MUTYH-associated adenomatous polyposis (MAP)

In 2002, Al-Tassan demonstrated a role for defective base-excision-repair (BER) in hereditary colorectal cancer(5). They identified bi-allelic germline mutations in the base-excision-repair gene *MUTYH* in a British family with three affected members and recessive inheritance of multiple colorectal adenomas and carcinoma. Further studies found bi-allelic *MUTYH* mutations in 26-29% of patients with 10-100 polyps and 7-29% of patients with 100-1000 polyps(74-76). Bi-allelic mutations have rarely been reported in patients with less than 10 adenomas, and in some apparently CRC-only patients(77;78). Based on these findings, patients with more than 10 adenomas should be referred for genetic counselling and mutation analysis of the *MUTYH*-gene should be considered. Bi-allelic *MUTYH*-mutations are usually associated with an attenuated polyposis phenotype. To date other intestinal malignancies and FAP-associated extra-intestinal lesions such as duodenal cancer, osteomas and CHRPE have been reported only sporadically in MAP-patients (79;80). Family members with mono-allelic mutations in *MUTYH* are probably not at increased risk of CRC, and therefore do not need colonoscopic surveillance(81).

QUESTION: *Which surveillance protocol should be recommended to patients with FAP due to bi-allelic MUTYH mutations?*

The decision regarding the age at which screening should start is based on the distribution of ages at diagnosis of CRC. CRC due to bi-allelic *MUTYH* mutations before the age of 30 years has been reported only once(79). Therefore, it appears justified to start screening from the same age as recommended in AFAP (between 18-20 years). Because patients may develop only a few adenomas and CRC is often localized in the proximal part of the colon, the Mallorca-group recommend performing colonoscopy at two-yearly-intervals in stead of sigmoidoscopy. Upper GI-endoscopy is advised starting from between 25 and 30 years of age. The recommended intervals between screening depend on the severity of disease (Table 7).

CONCLUSION: *The suggested surveillance protocol for MAP-patients is similar as for patients with AFAP (Category of evidence III, Grade of recommendation B)(see Table 4).*

QUESTION: *What is the appropriate surgical treatment of colonic polyposis in carriers of bi-allelic MUTYH mutations?*

Most patients with bi-allelic *MUTYH* mutations have an attenuated phenotype(76;79). Because of the small number of adenomas, in some patients it is possible to remove these polyps endoscopically. If surgery is required, an IRA will be sufficient in most cases to eliminate the cancer risk. However, if rectal polyposis is severe, an IPAA is advised.

Discussion

The guidelines for the management of FAP presented here are the result of intensive discussions among the participants of two workshops held in Mallorca in 2006 and 2007. Because most of the studies that form the basis for the guidelines were descriptive and/or retrospective in nature, many of the recommendations were based on expert opinion.

The identification of a mutated *APC*-gene as the cause of FAP in the early 1990's allowed presymptomatic diagnosis in families with an identified mutation. As a consequence those individuals that were found not to carry the mutation could be reassured and surveillance could be discontinued. Another way in which genetic information might be translated into clinical practice is in the decision making process

of surgical treatment. Studies have shown that the site of the mutation in the APC-gene may predict the risk of developing severe rectal polyposis and the need for subsequent proctectomy if a patient had colectomy with IRA. Using this genetic information, individuals may be identified with a low or high risk of developing significant rectal polyposis, and this can help in the decision between IRA and IPAA in difficult cases. However, the use of genetic information in the surgical decision making is controversial, because several studies have reported intrafamilial variation, which might be due to environmental factors or modifier genes. Moreover, in many patients a previously unknown (private) mutation is identified which cannot be used to predict the future course of the colorectal phenotype. Therefore, future prospective studies should be done to evaluate the utility of this genetic information in surgical practice.

In undiagnosed cases of FAP, the leading cause of death is colorectal cancer. The establishment of registries of FAP-families worldwide has encouraged participation in surveillance programs and has significantly reduced death from CRC. Nowadays, the prognosis of FAP patients appears to be increasingly determined by extracolonic features of FAP, especially duodenal cancer and desmoid tumours. Future studies should therefore focus on how the management of these tumours can be improved. Regarding duodenal polyposis, a few prospective studies have shown that the Spigelman classification can be used to identify patients who are at high risk of developing duodenal cancer. However, the risk of developing duodenal cancer reported for patients with Spigelman stage IV varied widely between these studies. Therefore, additional risk factors should be sought which can predict the development of duodenal cancer more precisely. The knowledge of such risk factors may also be helpful in decisions regarding the choice between local (endoscopic or surgical) treatment or a more definitive treatment like duodenectomy. Ideally, the latter option should be reserved for those patients with a high risk of developing duodenal cancer while local treatment may be indicated in those with a low risk.

All studies on the efficacy of drugs for desmoid tumours have been small and non-controlled. Therefore randomised controlled trials are needed to evaluate the effectiveness of the drugs that are currently used. Several studies have shown that surgery for colonic polyposis constitutes a risk factor for development of desmoid tumors. Future studies should address whether prophylactic treatment with sulindac and tamoxifen for 6 or 12 months postoperatively decreases the risk of desmoid especially in those patients with an increased risk of desmoids.

A possible way to improve the prognosis of patients with FAP further is early detection and treatment of the less common extra-intestinal cancers which are seen with increased frequency in individuals with FAP (see table 2). It has been reported that female FAP patients have a 2-3% lifetime risk of developing thyroid cancer (82). Based on these figures, some investigators have recommended surveillance of the thyroid by palpation and ultrasound, especially in women with FAP(83;84). However, other investigators consider the risk too low to justify such a program (85).

Surveillance for hepatoblastoma is also controversial. The risk for these tumours is about 1% and most tumours develop in the first year of life with a predominance in males (86). Future studies should evaluate whether surveillance programs for thyroid cancer and hepatoblastoma in FAP are effective and whether any gain in life-expectancy outweighs the potential psychosocial problems that may result(87). Small bowel cancers located distal to the ligament of Treitz, have occasionally been reported in FAP. In view of the development of new techniques for visualisation of the small bowel (videocapsule endoscopy, double ballon endoscopy) in recent years, the

question arises whether surveillance of the small bowel might be useful. In order to answer this question, studies are needed that evaluate the lifetime risk of developing such tumors.

The ideal treatment of patients with FAP would be pharmacological. Several studies have shown sulindac to be effective in reducing colorectal adenomas. Celecoxib is the only drug that has been shown to be effective in reducing duodenal adenomatosis. In view of the serious cardiovascular side-effects that have been reported in patients using one of the other selective COX-2 inhibitors (rofecoxib), some specialists are reluctant to prescribe celecoxib. However, provided that patients are screened for cardiovascular risk factors, the use of COX-2 inhibitors may be justifiable in special situations, for example, in patients with severe duodenal polyposis (Spigelman III and IV). Future studies should evaluate whether the potential risk of cardiovascular side-effects of celecoxib is significant in view of the possible use of these agents to reduce the cancer risk and avoid the morbidity and mortality associated with the endoscopic and surgical treatment for duodenal polyposis.

Finally, it has to be taken into account that although NSAIDs have been shown to reduce the number of adenomas, it has never been proven that these drugs also prevent the development of CRC. This is an important question because patients have been reported that developed cancer whilst being treated with NSAIDs, despite showing reduction of size and number of rectal adenomas(88).

In conclusion, the guidelines described in this manuscript may be helpful in the appropriate management of families with familial adenomatous polyposis. In order to further improve the care of these families, there is an urgent need for prospective controlled studies. The workshops in Mallorca have identified several collaborative studies that the group will focus on to clarify some of the current controversial issues in the clinical management of FAP.

Note: similar guidelines for the management of FAP have been published by a group of ten centres in the US (www.nccn.org/professionals)
